Many oomycete and fungal plant pathogens are obligate biotrophs, which extract nutrients only from living plant tissue and cannot grow apart from their hosts. Although these pathogens cause substantial crop losses, little is known about the molecular basis or evolution of obligate biotrophy. Here, we report the genome sequence of the oomycete *Hyaloperonospora arabidopsidis* (*Hpa*), an obligate biotroph and natural pathogen of *Arabidopsis thaliana*. In comparison with genomes of related, hemibiotrophic *Phytophthora* species, the *Hpa* genome exhibits dramatic reductions in genes encoding (i) RXLR effectors and other secreted pathogenicity proteins, (ii) enzymes for assimilation of inorganic nitrogen and sulfur, and (iii) proteins associated with zoospore formation and motility. These attributes comprise a genomic signature of evolution toward obligate biotrophy.

The oomycete *Hyaloperonospora arabidopsidis* (*Hpa*, formerly *Peronospora parasitica* or *Hyaloperonospora parasitica*) is a natural pathogen of *Arabidopsis thaliana* and a model for dissection of *A. thaliana* pathogen response networks (1, 2). *Hpa* belongs to a group of “downy mildew” pathogens, comprising more than 800 species that cause disease on hundreds of plant species (3). Downy mildew pathogens are related to other destructive oomycete plant pathogens (e.g., *Phytophthora* species) (4, 5). Oomycetes belong to the kingdom Stramenopila, which includes brown algae and diatoms. Although oomycetes and fungi share morphological and ecological similarities, they evolved independently to colonize plants.

*Hpa* hyphae grow between plant cells and establish feeding structures called haustoria, which includes brown algae and diatoms. Although oomycetes and fungi share morphological and ecological similarities, they evolved independently to colonize plants.

17,887 genes) (8). A total of 6882 predicted genes in Hpa had no identifiable ortholog in sequenced Phytophthora species or similarity to known proteins, and as such represent potentially lineage-specific genes. Some of these genes may play roles that are specific to biotrophy. For example, a novel family of secreted small, cysteine-rich proteins exists in Hpa (PPAT12/24-like) (Table 1) (11).

Pathogenicity genes were compared among Hpa and Phytophthora species, revealing that families encoding host-targeted, degradative enzymes (secreted proteinases, cell wall–degrading enzymes) are reduced in Hpa (Table 1). Two notable examples are the family 12 endoglucanases (EGL12) and pectin methyl esterases (Pect). Phylogenetic analyses delineated several EGL12 and Pect gene clades containing genes from P. sojae and P. ramorum but not Hpa (figs. S6 and S7). Because Hpa and P. sojae likely share a sister group relationship relative to P. ramorum (4, 5), it is probable that a number of EGL12 and Pect genes were lost from Hpa after divergence of the lineage leading to Hpa and P. sojae. Hydrolytic enzymes that target the host cell wall can release cell wall fragments that elicit host defenses. It is conceivable that in evolving a biotrophic lifestyle, Hpa has lost most of the secreted hydrolytic enzymes that were present in a hemibiotrophic ancestor.

Similarly, gene families encoding necrosis and ethylene-inducing (Nep1)-like proteins (NLPs) are significantly reduced in Hpa, compared with P. sojae and P. ramorum. NLPs in Phytophthora and Pythium can trigger plant cell death and defenses (12), which have been implicated in the transition from biotrophy to necrotrophy. Only three of the 13 oomycete NLP clades contain genes from Hpa. However, one clade contains an expanded family that is specific to Hpa (Fig. 1A). All 10 HaNLP genes are supported by transcriptional data. Of these, HaNLP3 is most closely related to the PsjoNIP and PiNPP1.1 proteins, but it did not induce necrosis in Nicotiana tabacum (Fig. 1B). These results suggest that downy mildew NL genes may have evolved a different function than in Phytophthora. Copy number reduction was also evident for genes encoding known pathogen-associated molecular patterns (PAMPs) such as sterol-binding elicitors (13) and carbohydrate-binding CBEL (cellulose-binding, elicitor, lectin-like) genes (14) (Table 1). These examples further suggest that selection for “stealth” (avoidance of host defenses) was a major force during downy mildew evolution.

Phytophthora genomes encode hundreds of potential effector proteins (9, 15, 16) with RXLR cell entry motifs (16–18) that likely function to suppress host defenses (19, 20). The Hpa genome contained 134 high-confidence effector gene candidates (HaRxL genes), including the known effector genes Atr1 and Atr13 (21, 22), significantly fewer than in the Phytophthora genomes (9, 15). Single-nucleotide polymorphisms arising from heterozygosity in v8.3 occurred at a rate 5 times as high in RXLR effector candidates [1 per ~500 base pairs (bp)] than in other genes (1 per ~2500 bp). Only 36% of the high-confidence Hpa effectors had significant matches in any Phytophthora genome (sequence similarity >30%), consistent with strong divergent selection on

Fig. 1. Diversity, evolutionary history, and functional analysis of oomycete necrosis and NLs. (A) Phylogeny of oomycete NLs. A consensus tree from the Bayesian inference is shown. Thick lines indicate high support in minimum evolution (>90), maximum likelihood (>90), and Bayesian inference (>0.95). Hollow lines indicate branches highly supported in at least two analyses. Branches with high support in less than two analyses are represented by thin lines. (B) An Hpa NL ortholog does not induce necrosis in plant leaves. NL genes were transiently expressed in Nicotiana tabacum by agroinfiltration.

Fig. 2. Synteny of conserved RXLR effectors. (A) Region around HaRxL23, spanning scaffold_9:467737-739923 (v6) and supercontig16:325445-40488 (v8.3.2) (B) Region around HaRxL13 and HaRxL136, spanning scaffold_150:3503-183330 (v6) and supercontig35:456072-268293 (v8.3.2). Colored boxes show order of gene models. Noncoding DNA is not represented. Dark green, ortholog; light green, orthologs found only in Phytophthora; dark brown, syntenic paralogs; light brown, syntenic orthologs found only in Phytophthora; white, syntenic gene families; dark blue, syntenic conserved RXLR effectors; cyan, syntenic RXLR effectors conserved only in Phytophthora; yellow, RXLR effectors not syntenic or conserved; blue-gray, other genes not conserved or syntenic. Black lines join syntenic genes with the same orientation; red lines join genes with reversed orientations. Staggered black lines in (A) show scaffold joins predicted from the synteny analysis. HaRxL23, HaRxL13, and HaRxL136 have 47, 38, and 40% amino acid identity, respectively, with their most similar Phytophthora ortholog within the normally hypervariable C terminus.
RXLR effector genes (15, 23). Moreover, Hpa effector genes generally were not located in syntenic locations relative to Phytophthora genomes, except for three families of effectors, which have unusually high levels of sequence conservation (Fig. 2).

As obligate biotrophs, downy mildews may have lost some metabolic pathways. We identified several potential metabolic defects in Hpa compared with P. sojae and P. ramorum (Fig. S9). For example, genes for nitrate and nitrite reductases, a nitrate transporter, and sulfite reductase were missing (fig. S10 and table S3), which is also a feature of the genomes of obligately parasitic powdery mildew fungi (24). Hpa also lacks genes required for synthesis of arachidonic acid and polyamine oxidases.

Flagellated zoospores are produced by many oomycetes (25). Contrastingly, several downy mildew lineages germinate by extending infective germ tubes from nonmotile conidiospores, although evidence exists for a rare zoosporic stage (26, 27). To conclusively determine whether spore motility has been lost from the Hpa lineage, we searched the Hpa genome for 90 flagellated-associated genes using Chlamydomonas sequences and their Phytophthora orthologs (28). No matches were identified in Hpa for any of these. Similarly, many Phytophthora adhesion-related genes are reduced in number or absent from Hpa, consistent with the lack of adherent cysts that normally develop from zoospores during infection.

Analysis of Hpa gene space revealed genomic signatures of major alterations in pathogenic strategy, metabolism, and development that occurred during the evolution of obligate biotrophy from a facultative, hemibiotrophic ancestor. Interestingly, some features of Hpa gene space (large numbers of secreted effectors, reduction in degradative enzymes, and loss of N and S assimilation) are mirrored in genomes of biotrophic fungi (24, 29, 30). These similarities indicate that convergent adaptations occurred during the independent evolution of biotrophy in fungal and oomycete lineages.

The Major Genetic Determinants of HIV-1 Control Affect HLA Class I Peptide Presentation

The International HIV Controllers Study‡†

Infectious and inflammatory diseases have repeatedly shown strong genetic associations within the major histocompatibility complex (MHC); however, the basis for these associations remains elusive. To define host genetic effects on the outcome of a chronic viral infection, we performed genome-wide association analysis in a multietnic cohort of HIV-1 controllers and progressors, and we analyzed the effects of individual amino acids within the classical human leukocyte antigen (HLA) proteins. We identified >300 genome-wide significant single-nucleotide polymorphisms (SNPs) within the MHC and none elsewhere. Specific amino acids in the HLA-B peptide binding groove, as well as an independent HLA-C effect, explain the SNP associations and reconcile both protective and risk HLA alleles. These results implicate the nature of the HLA–viral peptide interaction as the major factor modulating durable control of HIV infection.

HIV infection is characterized by acute viremia, often in excess of 5 million viral particles per milliliter of plasma, followed by an average 100-fold or greater decline to a relatively stable plasma virus load set point (1). In the absence of antiretroviral therapy, the level of viremia is associated with the rate of CD4+ T cell decline and progression to AIDS. There is substantial interperson variability in the virus load set point, with most individuals having stable levels exceeding 10,000 RNA copies/ml. Yet a small number of people demonstrate sustained ability to control HIV replication without therapy. Such individuals, referred to as HIV controllers, typically maintain stable CD4+ cell counts, do not develop clinical disease, and are less likely to transmit HIV to others (2).

To determine the genetic basis for this rare phenomenon, we established a multinational consortium (www.hivcontrollers.org) to recruit HIV-1 controllers, who are defined by at least three measurements of plasma virus load (VL) < 2000 RNA copies/ml over at least a 12-month period in the absence of antiviral therapy. We performed a genome-wide association study (GWAS) in the HIV controllers (median VL, CD4 count, and disease duration of 241 copies/ml, 699 cells/mm³, and 10 years, respectively) and treatment-naïve chronically infected individuals with advanced disease (median VL and CD4 count of 61,698 copies/ml and 224 cells/mm³, respectively) enrolled in antiviral treatment studies led by the AIDS Clinical Trials Group. After quality control and imputation on the basis of HapMap
